Abstract

We provide a set of comparable estimates for the rates of inflow to and outflow from unemployment using publicly available data for fourteen OECD economies. We then devise a method to decompose changes in unemployment into contributions accounted for by changes in inflow and outflow rates for cases where unemployment deviates from its flow steady state, as it does in many countries. Our decomposition reveals that fluctuations in both inflow and outflow rates contribute substantially to unemployment variation within countries. For Anglo-Saxon economies we find approximately a 20:80 inflow/outflow split to unemployment variation, while for Continental European and Nordic countries, we observe much closer to a 50:50 split. Using the estimated flow rates we compute gross worker flows into and out of unemployment. In all economies we observe that increases in inflows lead increases in unemployment, whereas outflows lag a ramp up in unemployment.

Keywords: Unemployment, Worker flows, Job Finding Rate, Separation Rate.

JEL-codes: E24, J6.

1 Introduction

Unemployment rates among developed economies have varied substantially both across time and across countries over the last 40 years. This variation in unemployment may occur as a result of variation in the rate at which workers flow into the unemployment pool, variation in the rate at which unemployed workers exit the unemployment pool, or a combination of the two. The relative contributions of changes in inflow and outflow rates to changes in unemployment have been abundantly documented for the U.S.¹ Less is known, however, about the driving forces of unemployment variation in other countries. Such a question is of interest because of the considerable variation in unemployment that has been observed in developed economies in recent decades, notably in Continental Europe. In this paper, we provide a detailed analysis of unemployment flows for fourteen developed economies using publicly available data.

In the first part of our analysis we describe how it is possible to derive measures of the rates of inflow² to and outflow from the unemployment pool using annual data from the OECD. To do this, we generalize the method developed by Shimer (2007), which makes use of time series for the number employed, the number unemployed, and the number unemployed less than five weeks to infer flow hazard rates for the U.S. A limitation that arises when applying this methodology outside the U.S. is that series on short duration unemployment can be noisy for countries in which short durations account for a small proportion of overall unemployment, such as in Continental Europe. To address this, we develop a method that exploits additional data on unemployment at higher durations to construct a set of comparable time series for the unemployment inflow and outflow rates across countries.

Our measures allow us to document a set of stylized facts on unemployment flows among developed economies. First, the average level of unemployment inflow and outflow rates varies substantially across countries. Interestingly, the results suggest a natural partitioning of economies into Anglo-Saxon, Nordic and Continental European. Anglo-Saxon and Nordic economies display high exit rates from unemployment, with monthly hazards that exceed 20 percent. In stark contrast, outflow rates among Continental European economies

¹See Elsby, Michaels, and Solon [2008], Fujita and Ramey [2008], Hall [2005a,b], Shimer [2007], and Yashiv [2007].

²Some recent literature on unemployment flows has referred to the rate of inflow into unemployment as the “separation rate” (Shimer, 2005a, b; Fujita and Ramey, 2008). We refer to it as the inflow rate for two reasons. First, a separation is typically taken to mean a quit or a layoff from an employer. In the presence of job-to-job transitions, such separations need not lead to an unemployment spell. Second, some unemployment spells originate from non-participation rather than a separation from employment.

are much lower—typically less than 10 percent at a monthly frequency. Symmetrically, unemployment inflow rates also vary considerably across countries. Anglo-Saxon and Nordic countries exhibit inflow hazards that exceed 1.5 percent at a monthly frequency. However, as with the observed levels of outflow rates, monthly inflow rates among Continental European economies are again much lower at around 0.5 to 1 percent. These observations confirm the diagnosis that European labor markets are *sclerotic* in the sense that they display much lower rates of reallocation of labor, as documented in Blanchard and Summers (1986), Bertola and Rogerson (1997), Blanchard and Wolfers (2000), and Blanchard and Portugal (2001).

In the second part of our analysis, we pose the question of how much of the observed variation in unemployment within each country can be accounted for by variation in the inflow rate into unemployment and variation in the outflow rate from unemployment respectively. To answer this, we provide a method for decomposing changes in the unemployment rate into contributions due to changes in the flow hazards that can be applied in countries with very different unemployment dynamics. Recent literature (Elsby, Michaels, and Solon [2009], Fujita and Ramey [2009], Petrongolo and Pissarides [2008]) has evaluated these contributions under the assumption that the unemployment rate is closely approximated by its flow steady state value. Under this assumption, contemporaneous unemployment variation may be decomposed into contributions related to contemporaneous logarithmic variation in inflow and outflow hazards. While this steady state assumption holds as a reasonable approximation in the U.S., we show that it can be very inaccurate in other developed economies, notably those of Continental Europe.

Reacting to this we show that, in cases where unemployment deviates from steady state, current variation in unemployment can be decomposed recursively into contributions due to current *and past* logarithmic changes in the inflow and outflow hazards. Intuitively, when unemployment is out of steady state, it can vary as a result of contemporaneous changes in the inflow and outflow rates, or as a result of dynamics driven by past changes in these flow hazards. Using our alternative decomposition, we obtain a much more accurate characterization of changes in unemployment rates across countries.

Application of our decomposition to our estimated time series for the flow hazard rates provides us with a second stylized fact on unemployment flows. Among all countries that we consider, fluctuations in both inflow and outflow rates contribute substantially to unemployment variations within countries. The relative contribution of each differs across countries, however. Among Anglo-Saxon economies we find approximately a 20:80 inflow/outflow split of unemployment variation, a result that echoes recent findings for the U.S. over the same

sample period. For Continental European and Nordic countries, however, we observe much closer to a 50:50 inflow/outflow split. Thus, a complete understanding of unemployment variation among our large sample of developed economies requires an understanding of the determinants of both the inflow rate as well as the outflow rate.

The final part of our empirical analysis uses the estimated flow hazard rates to compute measures of the *number* of workers flowing in and out of the unemployment pool (as opposed to the hazard rates for these flows).³ A third stylized fact that emerges from these results is that a geographical partitioning also applies to average worker flows across countries. Anglo-Saxon and Nordic countries exhibit annual worker flows in and out of unemployment that comprise more than 15 percent of the labor force. Among Continental European economies, on the other hand, worker flows typically involve less than 9 percent of the labor force, echoing the findings of Blanchard and Portugal (2001) and Bertola and Rogerson (1997).

We then analyze the dynamic relationship between these worker flows and unemployment within each country. Using a simple correlation analysis, we document a fourth stylized fact on unemployment flows among developed economies: The timing of the contributions of inflows and outflows to unemployment variation displays a remarkable uniformity across countries. In all economies we observe that increases in inflows lead increases in unemployment, whereas outflows lag a ramp up in unemployment, an observation that has been highlighted for the U.S. in earlier studies.⁴

Our findings that variation in unemployment inflows accounts for a substantial fraction of unemployment variation and is an important leading indicator for changes in unemployment dovetails with a recent literature on U.S. unemployment flows. A growing trend in modern macroeconomic models of the aggregate labor market has been to assume that the inflow rate into unemployment is acyclical (Hall [2005a,b], Shimer [2005] among others). Reacting to this, a number of recent studies has cautioned against this trend by documenting evidence for systematic countercyclical movements in unemployment inflows in U.S. data.⁵ Our findings

³Our analysis is not the first to estimate worker flows across countries. Other studies that examine worker flows for a subset of European countries include Albaek and Sørensen (1998) for Denmark; Bauer and Bender (2004) and Bachmann (2005) for Germany; Bertola and Rogerson (1997) for Canada, Germany, Italy, the U.K., and the U.S.; Burda and Wyplosz (1994) for France, Germany, Spain, and the U.K.; Petrongolo and Pissarides (2008) for France, Spain and the U.K.; and Pissarides (1986), Bell and Smith (2002), and Gomes (2008) for the U.K. Reichling (2005) reports estimates of the separation rate for a set of countries (see his Table 5) and also emphasizes that the separation rate is lower in European countries than in the U.S.

⁴See Darby, Haltiwanger, and Plant [1985, 1986], Blanchard and Diamond [1990], Davis [2006], Fujita and Ramey [2008].

⁵Recent studies that have emphasized this fact include Braun, De Bock, and DiCecio (2006); Davis (2006); Elsby, Michaels, and Solon (2008); Fujita and Ramey (2008); Kennan (2006); and Yashiv (2008). Older

show that this caution resonates all the more if we wish to understand the considerable variation in unemployment rates observed outside the U.S.

We conclude our analysis by providing some perspective on the relation between our results and modern models of unemployment flows. A common intuition is that the existence of stringent dismissal regulations in many European economies should depress the variability of layoffs, and hence limit the contribution of inflows to fluctuations in unemployment. Using a simple model in the vein of Mortensen and Pissarides (1994), we show that the economics is more subtle. While the presence of firing costs is likely to depress the *levels* of unemployment flows (a point first made by Bentolila and Bertola, 1990), the relative *volatility* of unemployment inflows does not depend directly on the magnitude of firing costs. Rather, we show that the role of inflows in unemployment variation depends on a number of less well-understood factors, such as the nature of idiosyncratic uncertainty, the form of the technology that matches unemployed workers to unfilled jobs, and the structure of production and product demand. However, the model does offer a tentative rationale for the greater role of inflows in Europe in the form of greater union bargaining power, which limits the responsiveness of job creation, and hence the unemployment outflow rate, to economy-wide shocks. Gaining a complete understanding of all of these components would enrich our understanding of the sensitivity of unemployment rates to fluctuations in overall economic activity, and of how this sensitivity is affected by labor market institutions and regulations. This is an important direction for further research.

The remainder of the paper is organized as follows. In section 2 we summarize the OECD data that we use throughout our analysis. In section 3, we describe our methodology for inferring the rates of inflow to and outflow from the unemployment pool using the OECD data. Application of this methodology provides individual time series for the unemployment flow hazards for each of the fourteen countries in our sample. In section 4, we pose the question of how much of the variation in unemployment within countries can be accounted for by changes in the inflow and outflow rates respectively. To answer this question, we derive a decomposition of unemployment variation that allows for unemployment to deviate from steady state. We show that allowing for such deviations is critical for understanding unemployment fluctuations outside the U.S. Section 5 presents evidence on the number of workers flowing in and out of unemployment, and documents stylized facts on the timing of the impact of worker flows on unemployment changes. Section 6 discusses how our empirical

studies that have documented this include Perry (1972); Marston (1976); Blanchard and Diamond (1990); and Baker (1992).

results relate to conventional models of unemployment flows. Section 7 summarizes and offers conclusions.

2 Data

Since a large part of our analysis is informed by the available data, we start by discussing the OECD samples that we use. These are taken from two different sources. First, we use annual measures of the unemployment stock by duration, taken from OECD (2008a).⁶ We then supplement these data with quarterly measures of the aggregate unemployment rate, taken from OECD (2008b). Both slices of data are based on the labor force surveys conducted in each of the countries in our sample.

The fourteen economies that we focus on are: Australia, Canada, France, Germany, Ireland, Italy, Japan, New Zealand, Norway, Portugal, Spain, Sweden, United Kingdom, and the United States. For all countries relatively long historical quarterly time series are available for the unemployment rate. Our focus on these economies is primarily driven by the length of the available requisite series for unemployment by duration. Throughout, we denote the fraction of the labor force in an unemployment spell of less than d months in month t by $u_t^{<d}$.⁷ For our analysis we use annual time series for $u_t^{<1}$, $u_t^{<3}$, $u_t^{<6}$, and $u_t^{<12}$. Note that we define these categories inclusively, in the sense that $u_t^{<3}$ includes $u_t^{<1}$, and so on. The starting year for the available series varies between 1968 (for the U.S.) and 1986 (for New Zealand and Portugal).⁸ For all countries, the data end in 2007.

An important advantage of using data from the OECD is that, even though the labor force surveys of these countries have different structures, the OECD data have been standardized to adhere to the same structure. This aids cross-country comparisons of our results.⁹

⁶The data are also publicly available on the web from <http://stats.oecd.org>.

⁷For many countries, data on unemployment duration initially were collected only once a year. More recently, mainly due to the standardization of Labor Force Surveys in the European Union, countries are collecting these data at a quarterly frequency. Because our aim is to construct historical time series that are as long as possible, we focus on annual time series.

⁸The initial year in the sample for each country is listed in Table 2.

⁹While the OECD goes to some lengths to standardize their unemployment measures, their procedures may not be perfect. For example, it is possible that workers who define themselves as out of the labor force in e.g. the U.S. might define themselves as unemployed in Europe. Addressing these important issues of standardization is beyond the scope of this paper.

3 The Ins and Outs of Unemployment in the OECD

At the heart of our analysis is a set of estimated annual time series of flow hazard rates into and out of unemployment for fourteen OECD countries. These time series are estimated using an extension of the method that Shimer (2007) developed for the United States. Shimer’s method cannot be applied directly to other OECD countries because the required data are not available. The extension that we introduce allows us to overcome this limitation and to produce annual time series for the rates of inflow to and outflow from the unemployment pool for a large subset of OECD countries.

3.1 Analytical Framework

The evolution over time of the unemployment rate, which we denote by u_t , can be written as:¹⁰

$$\frac{du_t}{dt} = s_t(1 - u_t) - f_t u_t, \quad (1)$$

where s_t is the monthly rate of inflow into unemployment, f_t is the monthly outflow rate from unemployment, and t indexes months.¹¹ As mentioned above, the data that we use in the remainder of the paper allow us to infer unemployment flows at an annual frequency. Thus, we would like to relate the continuous time evolution of unemployment in equation (1) to the unemployment rates that we observe at discrete annual intervals. Assuming that the flow hazards are constant within years,¹² and solving equation (1) forward one year allows us to do this:

$$u_t = \lambda_t u_t^* + (1 - \lambda_t) u_{t-12}, \quad (2)$$

where

$$u_t^* = \frac{s_t}{s_t + f_t} \quad (3)$$

¹⁰It is important to note that equation (1) implicitly assumes that all of the inflow into unemployment originates from employment. We have calculated a set of results taking into account non-participation. Except for the level of the average inflow rate, these results were very similar to those we present here. Details of these results, as well as an explanation of why this is the case are provided in the Appendix.

¹¹We define the flow hazards s_t and f_t in monthly terms to aid comparison with estimates reported in U.S. studies of unemployment flows.

¹²This assumption does lead to some smoothing out of high frequency variation in the flow hazards that we estimate. As many U.S. studies of unemployment flows have shown, and as we will confirm in our cross-country estimates, it is predominantly the inflow rate s_t that displays such high frequency variation. It follows that annual smoothing is likely to lead to an overstatement of the contribution of changes in the outflow rate f_t to unemployment variation. This works against a key finding of this paper that variation in the inflow rate s_t accounts for a substantial fraction of unemployment variation.

denotes the flow steady-state unemployment rate, and

$$\lambda_t = 1 - e^{-12(s_t+f_t)} \quad (4)$$

is the annual rate of convergence to steady state. In this way we can relate variation in the unemployment stock u_t in a given country over the course of a year to variation in the underlying flow hazards, s_t and f_t . To implement this, however, we need to obtain estimates of these flow hazards, to which we now turn.

Our method for estimating the outflow rate f_t is an extension of the method popularized by Shimer (2007). In his study of U.S. unemployment flows, he infers the monthly outflow probability F_t using the identity that the monthly change in the unemployment stock is given by

$$u_{t+1} - u_t = u_{t+1}^{<1} - F_t u_t. \quad (5)$$

Here $u_{t+1}^{<1}$ denotes the stock of unemployed workers with duration less than one month, and hence reflects the flows into unemployment; $F_t u_t$ reflects the flows out of unemployment. Solving for the monthly outflow probability, one obtains¹³

$$F_t = 1 - \frac{u_{t+1} - u_{t+1}^{<1}}{u_t}. \quad (6)$$

The monthly outflow probability is then related to the associated monthly outflow hazard rate, $f_t^{<1}$, through

$$f_t^{<1} = -\ln(1 - F_t). \quad (7)$$

3.2 Estimation of Flow Hazard Rates

In what follows we will see that the estimate of the outflow rate implied by equation (6) works well for countries in which the outflow rate from unemployment is relatively high, such as the U.S. However, in countries that exhibit low exit rates, such as those of Continental Europe, estimates based on equation (6) can be substantially noisy. The simple reason is that low outflow rates imply that very few unemployed workers at a point in time are in their first month of unemployment, which increases the sampling variance of the estimate of $u_{t+1}^{<1}$, and in turn leads to noisy estimates of f_t .

Our approach to this problem is to use the additional unemployment duration data

¹³Since the OECD database reports only quarterly data on the aggregate unemployment rate, we compute u_t by interpolating quarterly data.

available from the OECD to increase the precision of our estimate of f_t in countries where the outflow rate is low. To see how this may be done recall that the OECD data also report the unemployment stock at durations higher than one month. It follows that, analogous to the method detailed above, it is possible to write the probability that an unemployed worker exits unemployment within d months as

$$F_t^{<d} = 1 - \frac{u_{t+d} - u_t^{<d}}{u_t}. \quad (8)$$

As before, this can be mapped into an outflow rate estimate given by

$$f_t^{<d} = -\ln(1 - F_t^{<d})/d. \quad (9)$$

Given the available data, we can estimate $f_t^{<d}$ for $d = 1, 3, 6, 12$.¹⁴

It is important to clarify the interpretation of the outflow rate measures $f_t^{<d}$. It is tempting to interpret $f_t^{<d}$ as the outflow rate for unemployed workers of duration d . However, that is not an accurate interpretation. Rather, it is the hazard rate associated with the probability that an unemployed worker at time t completes her spell within the subsequent d months.

These four measures, $f_t^{<1}$, $f_t^{<3}$, $f_t^{<6}$, and $f_t^{<12}$, are not necessarily estimates of the same outflow rate. Only in the case where the outflow hazard is unrelated to the duration of an unemployment spell, i.e. if there is no duration dependence in outflow rates, are all four measures consistent estimates of the aggregate outflow rate from unemployment, defined as the average outflow rate among the entire unemployed population.¹⁵ However, if there is duration dependence in unemployment outflow rates in a given country, then estimates based on durations of unemployment greater than one month, $f_t^{<3}$, $f_t^{<6}$, and $f_t^{<12}$, will not yield consistent estimates of the average outflow rate among the unemployed.

For example, imagine that there exists negative duration dependence whereby the outflow rate declines with duration.¹⁶ In such an environment, we would expect to observe $f_t^{<1} >$

¹⁴The appendix contains a detailed description on how we estimate these rates combining the annual and quarterly data available.

¹⁵As has been emphasized since Kaitz (1970), duration dependence can arise through two channels. “True” duration dependence refers to the case where unemployment duration has a causal effect on the outflow rates of individual workers. In contrast, “spurious” duration dependence refers to the process of dynamic selection whereby workers with high exit rates leave unemployment faster than those with low exit rates, thereby generating a negative correlation between duration and outflow rates (Salant, 1977). The duration dependence that we refer to in this paper could arise from either of these two channels.

¹⁶In the U.S., for example, the finding of substantial negative duration dependence in unemployment exit

$f_t^{<3} > f_t^{<6} > f_t^{<12}$. To see why, consider the version of equation (8) which expresses the fraction of the unemployment stock in month t that exits within the next three months. The remaining unemployed workers that do not exit over these subsequent three months increasingly will be comprised of unemployed workers with low outflow rates, i.e. the high duration unemployed. This process of dynamic selection will imply that excessive weight will be placed on the low outflow rates of high duration unemployed workers in the estimate of $f_t^{<3}$, generating a downward bias in its estimate of f_t . This argument applies even more strongly to the estimates of $f_t^{<6}$ and $f_t^{<12}$.¹⁷

In light of this, we formally test for the presence of duration dependence in outflow rates by testing the hypothesis that $f_t^{<1} = f_t^{<3} = f_t^{<6} = f_t^{<12}$. The formal details are described in the Appendix, but our general approach is as follows. First, we derive the asymptotic distribution of the unemployment rates by duration as well as for the unemployment rates. We then apply the Delta method to compute the joint asymptotic distribution of the outflow rate estimates $f_t^{<d}$ with $d = 1, 3, 6, 12$. This allows us to formulate a simple Chi-squared test of the null hypothesis of no duration dependence.

For those countries for which we reject the hypothesis of no duration dependence, we follow the recent U.S. literature in using $f_t^{<1}$ as our estimate of the unemployment outflow rate. For countries with weak evidence for duration dependence for which we do not reject the null, we make use of all the additional information on the outflow rate contained in $f_t^{<3}$, $f_t^{<6}$, and $f_t^{<12}$ in order to obtain a more precise estimate of f_t . Specifically, we use our estimates of the asymptotic distribution of the outflow rate estimates, $f_t^{<1}$, $f_t^{<3}$, $f_t^{<6}$, and $f_t^{<12}$ to compute an optimally weighted estimate of the outflow rate that minimizes the mean squared error of the estimate.¹⁸

The results of the hypothesis test are reported in Table 2. While we find significant evidence of duration dependence in Anglo-Saxon and Nordic countries and Japan, we do not observe significant evidence among the Continental European countries in our sample.¹⁹

These results are consistent with other work that has estimated duration dependence across rates has been widely documented since Kaitz (1970). Most recently, Shimer (2008) has emphasized this stylized fact for the U.S.

¹⁷By the same token, the estimate of $f_t^{<1}$ that has been widely used in recent literature is also subject to this drawback, just to a lesser degree than the other three measures.

¹⁸The construction of these optimal weights is detailed in the Appendix.

¹⁹While our hypothesis test provides a natural rule of thumb, we implicitly rule in favor of the null when the hypothesis of no duration dependence cannot be rejected. This raises the question of the power of the test. In results that can be replicated in the spreadsheet that accompanies this paper, we observe that the test does indeed have high power among the Continental European economies for which we fail to reject the null, in the sense that the estimates of $f_t^{<d}$ are similar for all durations d .

countries. Machin and Manning (1999) fit a Weibull duration model to the duration structure of unemployment across countries. They report weak negative duration dependence in France and Spain in the 1990s, but strong negative duration dependence in Australia, the U.K. and the U.S. in the 1980s and 1990s. Using a similar approach on OECD data, Hobbijn and Şahin (2007) also find little evidence of duration dependence among Continental European economies, but substantial evidence among economies with high unemployment outflow rates. The result of our hypothesis test is that we use $f_t^{<1}$ as our estimate of the outflow rate for the Anglo-Saxon countries in our sample and the optimally weighted average of $f_t^{<1}$, $f_t^{<3}$, $f_t^{<6}$, and $f_t^{<12}$ for the remaining countries.

Given our estimate of the outflow rate, we compute the inflow rate s_t using the method pioneered by Shimer (2007). In particular, note that the expression for the annual unemployment rate in equation (2) is simply a nonlinear equation in the unemployment rates, u_{t+12} and u_t , and the flow hazard rates, s_t and f_t . We can thus solve equation (2) for the inflow rate. As emphasized by Shimer (2007) and subsequent work based on his method, this estimate of the inflow rate is robust to temporal aggregation bias in the measurement of unemployment inflows.

3.3 Evidence from OECD Data

The average unemployment inflow and outflow hazards over the sample periods for the whole sample of countries are reported in Table 2. A striking observation from these results is the substantial cross-country variation in both s_t and f_t . A particularly useful illustration of this point is in Figure 1, which displays the average values of s_t and f_t from Table 2 in graph form. Interestingly, one can discern a natural partition of developed economies between Anglo-Saxon, Nordic and Continental European economies.

Figure 1 reveals very high outflow rates among the Anglo-Saxon and Nordic economies. Among these countries the average monthly unemployment outflow hazard exceeds 20 percent. The economies of Continental Europe stand in stark contrast. Unemployment outflow rates in these economies lie below 10 percent at a monthly frequency. A similar picture develops for the estimates of the inflow rates in Figure 1. We observe high unemployment inflow hazards among the Anglo-Saxon and Nordic economies, which typically lie above 1.5 percent on a monthly basis. Likewise, inflow rates among the European economies are again much lower at around 0.5 to 1 percent per month.

Figure 1 also shows that there are both extremes and intermediate cases that are un-

derstated in this Anglo-Saxon/Nordic/Continental Europe taxonomy. For Japan, while the average unemployment outflow rate of 19 percent is similar to those in Anglo-Saxon and Nordic economies, its inflow rate is more comparable to those of Continental Europe. Another intermediate case is the U.K., which displays unemployment flows that lie halfway between the Anglo-Saxon and the Continental European models. Perhaps the most striking observation, however, is the outlier status of the U.S. With an average monthly unemployment outflow rate of nearly 60 percent and an average inflow rate of 3.5 percent, it exhibits transition rates at least 50 percent larger than the remainder of our sample of countries.

Figures 2 and 3 display the time series for the inflow and outflow hazards for each country in our sample. The transition rates are plotted on log scales since, as emphasized in the literature on unemployment flows, and as we will confirm in what follows, it is the logarithmic variation in s_t and f_t that places them on an equal footing with respect to fluctuations in the unemployment rate.

Figures 2 and 3 reveal that, in addition to significant cross-country variation in unemployment flows, there is also substantial variation in unemployment flow hazards over time within countries. Although there is a great deal of information contained in these figures, a number of observations come to light. First, there are important differences in the frequency of fluctuations in unemployment flows across economies. Among the Anglo-Saxon economies, a clear cyclical pattern is present, suggesting a substantial high frequency component to unemployment fluctuations in these countries. Among other economies, however, the variation in s_t and f_t occurs at a much lower frequency, and it is hard to differentiate cycle from trend.

Figures 2 and 3 are also indicative of how the relative contributions of variation in the inflow and outflow rates differ across countries. Specifically, the Anglo-Saxon economies appear to display relatively more variation in the outflow rate from unemployment, a point that has been emphasized in recent literature for the U.S. However, inspection of the time series for the Nordic and European economies reveals greater variation in the inflow rate, suggesting about an equal contribution of the ins and the outs to unemployment variation in these countries. Of course, this visual impression is only suggestive of the relative contributions of the inflow and outflow hazards to unemployment variation; we address this issue more formally in section 4. Before we do so, we first compare our estimates of unemployment transition rates with those reported in related literature.

3.4 Relation to Existing Evidence

Unemployment flows for the U.S. have been extensively studied in the literature. Almost all of these studies, including Elsby, Michaels, and Solon (2009), Fujita and Ramey (2009) and Shimer (2007), are based on data from the Current Population Survey. Since the OECD data that we use are also based on the same survey data, the levels of our estimated flow hazards are in line with these previous estimates.²⁰

The cross-country analysis of flow rates that is most closely related to the results in this paper is Hobijn and Şahin (2007). They use GMM to estimate average job-finding and separation rates for a broader sample of countries. Since they focus on average flow hazards, their analysis does not address the dynamic properties of the evolution of unemployment in these countries. The average flow transition rates that they obtain using their estimation method are almost identical to the those documented in Table 2.

The time series plotted in Figures 2 and 3 for countries other than the U.S. also are qualitatively similar to previous results based on microdata for individual countries. Our estimates for the U.K. are consistent with the declining employment to unemployment (E–U) and rising unemployment to employment (U–E) transition rates estimated using U.K. Labour Force Survey data from the early 1990s on (Bell and Smith [2002], Gomes [2008], and Petrongolo and Pissarides [2008]). The trends we find for Germany are consistent with Bachmann (2005) who uses German social security data to estimate a sharp rise in the E–U transition rate and a decline in the U–E hazard in the early 1990s. In addition, the estimated time series for Spain correspond very closely to those reported in Petrongolo and Pissarides (2008) using Spanish Labor Force Survey data. Reichling (2005) reports estimates of the separation rate for a set of countries (see his Table 5) and also emphasizes that the separation rate is lower in European countries than in the U.S.

There are also several cross-country studies that provide structural estimates of search models that include estimated flow hazards. Two examples of these are Ridder and van den Berg (2003) and Jolivet, Postel-Vinay Robin (2006). Because they are based on structural models, the estimated transition rates in these papers do not correspond exactly to the flow rate concept we use here. However, the qualitative ranking of countries in terms of the levels of inflow and outflow rates are very similar to ours. For example, Italy is estimated to have the smallest outflow rate, the U.S. the highest, with the U.K lying between the U.S. and the Continental European countries.

²⁰One exception is Hall [2005], who employs a broader definition of unemployment than the usual Current Population Survey definition. Consequently he estimates a lower outflow rate.

3.5 Institutions and Unemployment Flows

Thus far we have emphasized the between-country differences in the overall levels of labor market flow transition rates. For many countries in our sample, however, changes in labor market institutions and policies have led to persistent shifts in the degree of worker turnover. In this section, we highlight some prominent examples of such institutional changes and deregulations, and relate them to our measures of unemployment flows and to the previous literature.

Perhaps the most dramatic institutional change witnessed among the economies in our sample was the reunification of Germany in 1990. Our data suggest that this was associated with a dramatic increase in unemployment inflows in 1991, reaching a peak in 1992, and remaining high thereafter. This is consistent with related trends highlighted in available literature on the reunification. In particular, the opening up of borders in the east led to a surge of migration into western Germany in the early 1990s, a trend that has continued to the present day. Hunt (2008) reports that five percent of the eastern population emigrated from east to west over this period. It is likely that many of these migrants began to seek work in the west, thereby raising the unemployment inflow rate.

Besides German reunification, one of the most important developments in Continental European labor markets has been the introduction and expansion of fixed-term, or temporary, contracts in a number of countries starting in the 1980s. Here we discuss two leading examples: Spain and France. Fixed-term contracts were expanded in both countries during the 1980s as a politically feasible means of reducing firing costs. Previous literature has emphasized that the expansion of these contracts should positively affect rates of inflow into unemployment (e.g. Blanchard and Landier, 2002).

How do trends in the incidence of fixed-term contracts documented in previous research line up with trends in the unemployment inflow rate depicted in Figure 3? For Spain, Bentolila, Dolado and Jimeno (2008) document the rapid expansion in the use of fixed-term contracts from 1987 to 1993, increasing from approximately 15 to over 30 percent of total employment. In addition, Bentolila et al. summarize a series of countervailing reforms starting in 1994 that relaxed firing costs in permanent contracts and limited the use of fixed term contracts. Consistent with these trends, our data for Spain reveal a marked rise in the unemployment inflow rate from 1987 to 1993, which was subsequently reversed during the mid to late 1990s. Thus, conventional wisdom on the effects of fixed term contracts lines up well with aggregate trends for unemployment inflows in Spain.

The same is not true for France. Blanchard and Landier (2002) show that the incidence

of fixed-term contracts expanded in France from the mid-1980s to 2000, from 1.4 to 10.8 percent of employment. While the inflow rate for France rose through to the early 1990s, it declined during the mid to late 1990s. A similar trend is documented for France by Petrongolo and Pissarides (2008), using unemployment benefit claims data. Blanchard and Landier highlight possible reasons for this. The first is that the incidence of fixed-term contracts in the aggregate is much more limited in comparison to Spain, hence limiting the effects on unemployment inflows. Second, Blanchard and Landier emphasize that temporary contracts particularly affected young workers in France, many of whom are not recorded as unemployed, but rather as students.

Our final example of institutional change relates to changes in the generosity of unemployment benefits that occurred in a number of countries in our sample. We again highlight two examples: the United Kingdom and Sweden. Both countries limited the generosity of unemployment compensation during the 1990s as a response to persistently high unemployment rates.

In the U.K. this occurred in the form of the the Jobseeker's Allowance (JSA) reform of October 1996.²¹ This reform reduced the duration of eligibility for unemployment benefits, and substantially increased job search requirements for the continued receipt of benefits. Standard models of job search predict that such a reform would increase the search intensity of continuing unemployed claimants, and would shift some low search effort unemployed into other social insurance programs (see, for example, Manning, 2009). Both would lead to an increase in the rate of outflow from unemployment. Consistent with this, the measured outflow rate for the UK in Figure 2 exhibits a sharp upward movement in 1997 and after. It is particularly important in this context to reiterate the message of footnote 2 above that we do not measure the job finding rate, but rather the rate of exit from unemployment. Thus, our measures in Figure 2 do not necessarily have the implication that the JSA improved job finding prospects in the UK. Indeed, previous research by Manning (2009) and Petrongolo (2009) suggests that, on the contrary, the main impact of the JSA reform was to shift claimants into other forms of social assistance.

In the case of Sweden, unemployment rose to historic levels following the Swedish economic crisis of the early 1990s. Figure 2 documents the substantial rise in the inflow rate, and decline in the outflow rate that accompanied the crisis. Facing a mounting budget deficit, various expenditure-cutting reforms were implemented, including reductions in the generosity of unemployment insurance benefits. At the beginning of 1990s, the UI replace-

²¹For a detailed analysis of the labor market reforms in the U.K. see Pissarides (2003).

ment rate in Sweden was 90%. Sweden reduced the generosity of its UI system by lowering the replacement rate to 80% in 1993.²² Consistent with this, we observe a gradual increase in the outflow rate in Sweden in early 1990s. The increase in the outflow rate is consistent with the findings of Carling, Holmlund and Vejsiu (2001) who study the effect of the reform on the unemployment to employment transition rate. They find that the unemployment to employment transition rate increased by around 10 percent in 1996.

4 Decomposing Unemployment Fluctuations

In this section, we formulate and apply a formal decomposition of changes in unemployment into parts due to changes in the inflow and outflow rates for each country. Our decomposition allows for deviations of the actual unemployment rate from its flow steady-state value. We show that allowing for such deviations is important for understanding unemployment fluctuations in many, especially European, countries. We use the annual time series on inflow and outflow rates, presented above, to conduct this decomposition. Because we use annual data in what follows, time, t , is denoted in years rather than months in the remainder of this paper.

4.1 Analytical Framework

As mentioned above, an important aim of this paper is to understand the proximate driving forces behind variation in unemployment rates across countries. As previous literature has shown, such a task is relatively straightforward for the U.S.²³ The reason is that unemployment dynamics are uncommonly rapid in the U.S.—that is, $s_t + f_t$ is a relatively large number in the U.S. The formal implication of this is that the rate of convergence of the unemployment rate to its flow steady state value in equation (2), $\lambda_t = 1 - e^{-12(s_t+f_t)}$, is very close to one in the U.S. In this case, the unemployment rate can be approximated very closely by its flow steady state value,

$$u_t \approx u_t^* = \frac{s_t}{s_t + f_t}, \text{ and } \lambda_t \approx 1. \quad (10)$$

²²The replacement rate was further reduced to 75% in 1996, but this was reversed in 1997, when the replacement rate was increased back to 80%.

²³See Elsby, Michaels and Solon (2009), Fujita and Ramey (2009) and Pissarides (2007), among others.

As emphasized in Elsby, Michaels and Solon (2009), log differentiation of the latter implies

$$d \ln u_t \approx (1 - u_t)[d \ln s_t - d \ln f_t]. \quad (11)$$

Thus, in countries with labor markets characterized by fast unemployment dynamics, a simple decomposition of unemployment variation presents itself: The relative contributions of the inflow and outflow rates to unemployment variation can be gleaned from comparing the contemporaneous logarithmic variation in the two flow hazard rates.

Based on the evidence we found above, one might anticipate that the approximations that underlie the decomposition of unemployment variation based on (11) work well among the Anglo-Saxon and Nordic economies, which display relatively high rates of inflow and outflow. However, the evidence also suggests that there is good reason to hesitate in applying equation (11) as a decomposition of unemployment variation in Continental Europe. The reason is that the unemployment flow hazards in these economies are very low, especially relative to the U.S. Inspection of equation (2) reveals that, for Continental Europe, the flow steady-state unemployment rate is therefore likely to be a poor approximation to the actual unemployment rate.

Reacting to this, we devise a decomposition of unemployment changes that holds even when unemployment is out of steady state. Our approach uses equation (2) as its starting point. We show in the Appendix that a log-linear approximation to (2) allows us to express the log change in the unemployment rate recursively as

$$\Delta \ln u_t \approx \lambda_{t-1} \left\{ (1 - u_{t-1}^*) [\Delta \ln s_t - \Delta \ln f_t] + \frac{1 - \lambda_{t-2}}{\lambda_{t-2}} \Delta \ln u_{t-1} \right\}. \quad (12)$$

This decomposition distinguishes between changes in the steady state due to current changes in the inflow and outflow rates, and changes in the unemployment rate due to deviations from the steady state caused by past changes in the flow rates.

A number of aspects are worth noting about equation (12). First, if unemployment dynamics are very fast, so that $s_t + f_t$ is high and λ_t is close to one for all t , then equation (12) reduces to the steady-state decomposition implied by (11). In addition, a particularly intuitive way of understanding (12) is to consider the case where $\lambda_t = \lambda$ for all t . In that case, the log change in the unemployment rate in (12) is a distributed lag of contemporaneous and past log changes in the inflow rate s_t and the f_t . This highlights a potential pitfall of applying the steady-state decomposition in (11) to unemployment flows

in economies, such as those of Continental Europe, with slow unemployment dynamics: Out of steady state, contemporaneous variation in the unemployment rate is driven both by contemporaneous *as well as lagged variation* in the flow hazards. We will see that, by ignoring these lag effects, the steady-state decomposition can lead to misleading conclusions on the relative contributions of the inflow and outflow rate to changes in unemployment.

In principle, the non-steady-state decomposition in equation (12) can be used to assess the relative contributions of inflow and outflow rates for any given change in the unemployment rate at any time for any given country. Clearly, however, given the wealth of information in our dataset, performing such a decomposition for every unemployment episode in every country would be excessive. Thus, we need a method of summarizing the relative contributions of the ins and outs of unemployment.

Fujita and Ramey (2009) formulate such a summary method for the U.S. using the steady-state decomposition. Specifically, they compute the following β values:

$$\beta_f^* = \frac{\text{cov}(\Delta \ln u_t, -(1 - u_{t-1}^*)\Delta \ln f_t)}{\text{var}(\Delta \ln u_t)} \quad \text{and} \quad \beta_s^* = \frac{\text{cov}(\Delta \ln u_t, (1 - u_{t-1}^*)\Delta \ln s_t)}{\text{var}(\Delta \ln u_t)}, \quad (13)$$

where a superscript * indicates that these are based on the assumption that observed unemployment is closely approximated by its steady-state value. If this assumption holds, β_f^* and β_s^* should approximately sum to one.

We extend Fujita and Ramey's β s to the decomposition of unemployment changes out of steady state based on equation (12). In particular, for each country in our sample we compute

$$\beta_f = \frac{\text{cov}(\Delta \ln u_t, C_{ft})}{\text{var}(\Delta \ln u_t)}, \quad \beta_s = \frac{\text{cov}(\Delta \ln u_t, C_{st})}{\text{var}(\Delta \ln u_t)}, \quad \text{and} \quad \beta_0 = \frac{\text{cov}(\Delta \ln u_t, C_{0t})}{\text{var}(\Delta \ln u_t)}, \quad (14)$$

where C_{ft} , C_{st} , and C_{0t} denote the respective *cumulative* contributions of contemporaneous and past variation in the inflow rate, the outflow rate, as well as the initial deviation from steady state at time $t = 0$. Consistent with (12), they are defined recursively by

$$C_{ft} = \lambda_{t-1} \left[-(1 - u_{t-1}^*)\Delta \ln f_t + \frac{1 - \lambda_{t-2}}{\lambda_{t-2}} C_{ft-1} \right] \quad \text{with } C_{f0} = 0, \quad (15)$$

$$C_{st} = \lambda_{t-1} \left[(1 - u_{t-1}^*)\Delta \ln s_t + \frac{1 - \lambda_{t-2}}{\lambda_{t-2}} C_{st-1} \right] \quad \text{with } C_{s0} = 0, \quad (16)$$

and

$$C_{0t} = \frac{\lambda_{t-1}(1 - \lambda_{t-2})}{\lambda_{t-2}} C_{0t-1} \text{ with } C_{00} = \Delta \ln u_0. \quad (17)$$

If the decomposition fully captures fluctuations in the unemployment rate then $\beta_s + \beta_f + \beta_0 = 1$.

4.2 Accounting for Unemployment Fluctuations in the OECD

In order to illustrate why it is important to take into account deviations from steady state for many countries, consider Figure 4. This plots the actual unemployment rate, u_t , as well as the flow-steady-state unemployment rate, u_t^* , for the four countries that are studied by Petrongolo and Pissarides (2008), namely France, Spain, the U.K., and the U.S. As has been emphasized in the recent literature, for the U.S. the actual unemployment rate is virtually identical to the steady-state unemployment rate. However, we observe that this is not the case for the other three countries.

Another way of seeing this is to look at the second column of Table 3. This lists the standard deviation of the logarithmic deviation of unemployment from steady state for each of the countries in our sample. Table 3 reveals that these deviations tend to be small among Anglo-Saxon economies which have high inflow and outflow rates, with the exception of the U.K. All other countries exhibit substantial deviations of unemployment from its flow-steady-state value.

To see what happens when one applies the decomposition based on the steady-state assumption to a country that substantially deviates from steady state, consider the top panel of Figure 5. It depicts the steady-state decomposition of $\Delta \ln u_t$ into parts due to changes in the inflow rate, the outflow rate, and a residual part that is due to approximation error for France. As can be seen from this figure, the residuals from the steady-state decomposition are very large. In fact, in this case we observe that $\beta_f^* + \beta_s^* = 1.20$ rather than 1. Thus, if one calculates β_s^* and imputes $\beta_f^* = 1 - \beta_s^*$, then one would underestimate β_f^* by 0.20 because of the approximation error induced by deviations from steady state.²⁴

The bottom panel of Figure 5 depicts the non-steady-state decomposition for France. As this figure shows, the residuals are very small and the magnitudes of the parts due to the flow rates decrease relative to the steady-state decomposition. In the first five years of the sample a non-trivial part of unemployment fluctuations in France was due to the labor

²⁴In their analysis, Petrongolo and Pissarides (2008) implicitly acknowledge this drawback by eliminating the periods for which the deviation of the unemployment rate from its flow steady state value is large.

market not being in steady state in 1976. This is reflected by the contribution of the initial value to the changes in the unemployment rate.

The results of our non-steady-state decomposition based on equations (12), (14) and (15) for each country are presented in Table 3. For purposes of comparison, we also include the results from applying the steady-state decomposition. The results in Table 3 are notable from a number of perspectives. First, as anticipated above, we observe that the steady-state decomposition in equation (13) works quite well for economies with fast unemployment dynamics, such as the Anglo-Saxon and Nordic economies, in the sense that the β_s^* and β_f^* approximately sum to one for these economies. In contrast, the steady-state decomposition performs very poorly among economies with slow unemployment dynamics: The sum of the estimated β_s^* and β_f^* consistently lies above one for these countries, rendering the steady-state decomposition uninformative in determining the driving forces of unemployment variation.²⁵

As anticipated by the results for France in Figure 5, the results of our non-steady-state decomposition reveal that this problem is substantially reduced when we take into account the lag structure of the effects of changes in inflow and outflow rates on unemployment: The residual variance of log changes in unemployment is closer zero for all countries, and especially so among economies with slow unemployment dynamics. Thus, taking account of the dynamic effects of changes in the unemployment flow hazards on the unemployment rate is important for inferring the proximate driving forces of unemployment fluctuations. In this way, the non-steady-state decomposition summarized in equations (12), (14) and (15) is a useful contribution to the analysis of unemployment flows across countries.

The formal results of the non-steady-state decomposition in Table 3 in many ways confirm the suggestive picture that one can discern from the time series in Figure 2 and 3. Among the Anglo-Saxon economies of Australia, Canada, New Zealand and the U.S., we observe that variation in the outflow rate accounts for the majority (though not all) of the variation in the unemployment rate over the respective sample periods. In particular, we find something like a 20:80 inflow/outflow accounting for unemployment variation for these economies.

However, variation in the inflow rate plays a much larger role among other economies. In fact, we find much closer to a 50:50 inflow/outflow split for the Continental European, U.K., Nordic and Japanese economies. These observations are an interesting addition to the debate that has progressed for the U.S. Recent studies have cautioned against the neglect of variation

²⁵The main reason that the steady-state decomposition consistently explains more than 100% of unemployment variation is that contemporaneous changes in log flow hazards in reality have only a partial contemporaneous effect on current unemployment, determined by $\lambda_{t-1} < 1$ (see equation (12)). The steady-state decomposition erroneously attributes their full effect contemporaneously.

in unemployment inflows as an important driving force for changes in unemployment in the U.S. context.²⁶ The results summarized in Table 3 show that this caution resonates louder still if we wish to understand the considerable variation in unemployment rates outside of the U.S.

The latter point is important for our understanding of the economics of unemployment. The relative abundance and ease of access to relevant data for the U.S. have led to a wealth of research that documents the proximate driving forces for variation in the U.S. unemployment rate. However, the variation in unemployment in the U.S., though substantially cyclical, is dwarfed by the unemployment experiences among many European economies. A prominent example is Spain, which faced unemployment rates that varied from below 5 percent in the 1970s to 25 percent in the 1990s (see Figure 4). Our results suggest that, in order to understand the substantial variation in unemployment rates among European economies, it is necessary to understand both the variation in the outflow rate from unemployment as well as the inflow rate.

4.3 Relation to Existing Evidence

A number of studies have documented the contributions of changes in inflow and outflow rates to unemployment variation in the U.S. (see Elsby, Michaels and Solon, 2009; Shimer, 2007; and Fujita and Ramey, 2009). A natural question is whether the results of our decomposition are similar to these related findings. Recall from Table 3 that we find approximately a 20:80 inflow/outflow contribution to unemployment variation in the U.S. over the period 1968 to 2007 covered by our data. At first blush, this finding can seem different from those reported in prior research.²⁷ Fujita and Ramey (2009), for example, report a greater role for inflows, accounting for as much as 56 percent of unemployment fluctuations.

The most comparable previous estimates of inflow and outflow rates to the ones we present here are those derived by Elsby, Michaels and Solon (2009). Using their quarterly analogs of our annual estimates yields an estimated inflow contribution of 27 percent over the period 1968 to 2004, a little larger than our estimates based on annual data. This

²⁶See Braum, De Bock and DiCecio (2006), Elsby, Michaels and Solon (2009), Fujita and Ramey (2009), and Yashiv (2008).

²⁷An exception is Shimer (2007) who reports an inflow contribution of 18 percent for the period 1967 to 2007 using a slightly different decomposition method (see his Table 1, column 2). Shimer's method is analogous to ours, except that he uses the sample average flow hazards as the expansion point for his approximation. Specifically, he computes two counterfactual unemployment rates. The first fixes the inflow rate at its sample average and allows the outflow rate vary as it did in the data; the second does the opposite. He then decomposes the variance of unemployment into components related to these two counterfactuals.

confirms the intuition foreshadowed in footnote 12 that the use of annual data leads to some smoothing of high frequency fluctuations in the inflow rate, leading to an understatement of the inflow contribution to unemployment variation. However, the understatement is not nearly as severe as one might imagine from a simple comparison with Fujita and Ramey (2009).²⁸

Comparatively little research has studied the contributions of the changes in the inflow and outflow rates to the fluctuations in unemployment across countries. A notable exception is Petrongolo and Pissarides (2008), who study the dynamics of unemployment in three European countries: the U.K., France and Spain. They implement a different method for treating deviations of actual unemployment from its flow steady state, by dropping observations for which that deviation is large. Despite this, our results line up well with their findings for the U.K. and Spain. Using U.K. Labor Force Survey microdata for the period 1993 to 2005, they report an inflow contribution of 0.48. Over the same period, we estimate a steady state inflow contribution of 0.43 for the U.K. Similarly, using Spanish Labor Force survey data for the period 1987 to 2006, Petrongolo and Pissarides report an average inflow contribution of 0.43. The corresponding value in our calculations is 0.40. It is reassuring that these two perspectives on the data yield similar answers: The OECD data for the U.K. and Spain are annual measures based on the respective quarterly labor force surveys that Petrongolo and Pissarides use. This suggests that there is little slippage in using annual data to measure the flow contributions to unemployment fluctuations for these European countries.²⁹

²⁸The relatively large inflow contributions reported by Fujita and Ramey can be traced to a number of factors. First, their larger estimated inflow contributions are based on different data sources that use longitudinally linked monthly microdata from the Current Population Survey (the so-called gross flows data). Second, Fujita and Ramey decompose changes in *steady state* unemployment rather than the realized unemployment series, which in practice accentuates the estimated inflow contribution. Third, the sample periods reported by Fujita and Ramey do not coincide with ours. Relaxing all these differences yields an inflow contribution of 27 percent.

²⁹Petrongolo and Pissarides' results for France based on unemployment claims data do not line up as well with our estimates. They report an inflow contribution of 0.2 for the years 1991 to 2007, smaller than our analogous estimate of 0.5. We suspect that this discrepancy arises because the OECD data that underlie our estimates are based on French Labor Force Survey data, rather than the claimant data used by Petrongolo and Pissarides. This is consistent with results reported by Petrongolo and Pissarides' for the U.K. Their measured inflow contribution based on U.K. unemployment claims data for the period 1993Q2 to 2005Q3 is 0.25, much less than their estimate of 0.48 based on the U.K. Labor Force Survey.

5 Worker Flows

So far, we have focused on the flow hazard rates for worker transitions in and out of unemployment. These flow rates, in turn, generate actual worker flows into and out of unemployment. In this final part of our analysis, we construct annual time series of worker flows for the fourteen OECD countries in our sample. We use these time series to uncover a very robust stylized fact across countries: Inflows lead changes in unemployment, while outflows lag.

5.1 Analytical Framework

The annual flow hazard rates that we presented before can be used to compute the total outflows out of unemployment and inflows into unemployment. Let \mathcal{F}_t be the total number of workers that flows out of the unemployment pool in year t as a fraction of the labor force, and let \mathcal{S}_t be the total inflows into unemployment.

Given (1), these flows can be written as

$$\mathcal{F}_t = 12f_t u_t^* + \lambda_t (1 - u_t^*) (u_t - u_t^*), \text{ and } \mathcal{S}_t = 12s_t (1 - u_t^*) - \lambda_t u_t^* (u_t - u_t^*). \quad (18)$$

By construction, the flows are such that the increase in the unemployment rate is the difference between the inflows and the outflows, i.e.

$$\Delta u_t = \mathcal{S}_t - \mathcal{F}_t. \quad (19)$$

A large number of studies (Darby, Haltiwanger, and Plant [1986], Davis [1987, 2006], Blanchard and Diamond [1990], Merz [1999], and Fujita and Ramey [2009]) has noted two key stylized facts about worker flows in the U.S. The first is that gross flows increase when unemployment increases. The second is that changes in inflows, $\Delta \mathcal{S}_t$, tend to lead the changes in outflows, $\Delta \mathcal{F}_t$, as well as changes in the unemployment rate, Δu_t . In what follows, we confirm that these stylized facts for the U.S. also hold for many other developed economies.

5.2 Evidence on Worker Flows in the OECD

Figures 6 and 7 depict the time series for our estimates of the number of workers flowing into unemployment, \mathcal{S}_t , and the number flowing out, \mathcal{F}_t , together with the unemployment rate for each country in our sample. In line with the differences in the flow hazard rates s_t and f_t between Anglo-Saxon Countries and Continental Europe, we find very large differences

in average worker flows between these groups of countries as well. The second column of Table 4 contains the average worker flows for all countries in our sample. These echo the stark geographical partitioning of labor market flows that we detailed above for the flow hazard rates across countries. Anglo-Saxon countries exhibit annual worker flows in and out of unemployment that comprise more than 15 percent of the labor force. The U.S. is once more a conspicuous outlier with average annual worker flows of 40 percent of the labor force. At the opposite end of the spectrum again lie the economies of Continental Europe with worker flows that typically account for less than 9 percent of the labor force.

In addition, a prominent visual pattern to the timing of changes in these flows emerges from Figures 6 and 7. It can be seen that increases in the unemployment rate are often preceded by rises in the number of workers flowing into the unemployment pool, followed by a commensurate rise in the outflow. Thus, in most countries we observe that gross flows increase when unemployment rises, and that inflows tend to lead outflows, just as observed in U.S. data.

This observation can be seen more formally using a simple correlation analysis. The last six columns of Table 4 report the contemporaneous, lead, and lag correlations between the changes in the flows and changes in the unemployment rate. These correlations tell the following story. In the year prior to a rise in unemployment, inflows into the unemployment pool rise—the one year lead correlation between changes in inflows and contemporaneous changes in unemployment is positive in almost all economies. Moreover, inflows remain high in the year that unemployment rises—the contemporaneous correlation between changes in inflows and changes in unemployment are positive for all countries. In the year following an unemployment ramp up, outflows begin to rise—the one year lag correlation between changes in outflows and contemporaneous changes in unemployment is positive in all economies.

Thus, just like studies that use monthly data for the U.S., we find that changes in inflows tend to lead changes in the unemployment rate in the annual data we use. What emerges from our results on worker flows is that, even though the OECD economies have very different levels of flows, the cyclical behavior of worker flows across countries is very similar. Economic downturns, in which the unemployment rate increases, first see an increase in workers flowing into unemployment, rather than a decline in the number of workers flowing out of it. Subsequently, the outflows increase as the economy recovers.

These results have stark implications for popular models of the aggregate labor market. An important recent trend in these models has been to assume that inflow rate s_t into unemployment is constant over the business cycle (Hall [2005a,b], Blanchard and Gali

[2006], Gertler and Trigari [2006], Krusell, Mukoyama, and Şahin [2009], for example). In the context of these models, increases in unemployment during recessions are driven entirely by declines in the job finding hazard, f_t .

This assumption has important implications for the dynamic properties of worker flows over the cycle. A rich literature on unemployment flows in the U.S. has emphasized that such models imply that increases in the unemployment rate are preceded by reductions in the number of workers flowing out of the unemployment pool, \mathcal{F}_t (Darby, Haltiwanger, and Plant, 1985, 1986; Blanchard and Diamond, 1990; Davis, 2006). Consequently, reductions in outflows are predicted to *lead* increases in the unemployment rate in this class of models. In addition, because the inflow rate s_t is assumed constant, these models also imply that the number of workers flowing into the unemployment pool \mathcal{S}_t will decline modestly in the wake of a recession as the employment rate $1 - u_t$ falls, so that changes in \mathcal{S}_t *lag* changes in the unemployment rate. Thus, models that assume a constant inflow rate have two important predictions with regard to worker flows: (i) when unemployment goes up gross worker flows decline, and (ii) outflows lead changes in unemployment, while inflows lag.

The studies of worker flows in the U.S. cited above have established that neither of these theoretical implications is borne out by the data for the U.S. This has led researchers to challenge the empirical relevance of such models in the U.S. context (Davis [2006]; Fujita and Ramey [2009]; Ramey [2008]). Our results reveal that the observation of increased inflows as a leading indicator of increased unemployment, far from being unique to U.S. data, is something close to a stylized fact for all modern developed labor markets.

These results confirm and reinforce earlier findings based on earlier periods for subsets of the European countries that we study. Using Portuguese microdata from the early 1990s, Blanchard and Portugal (2001) emphasize that the levels of worker flows are much lower in Portugal relative to the U.S. Similar findings are reported by Bertola and Rogerson (1997, Table 3) who document reduced worker flows in Italy and Germany relative to Anglo-Saxon counterparts using OECD data for 1988. Using data from France, Germany, Spain, and the U.K. up to the early 1990s, Balakrishnan and Michelacci (2001) and Burda and Wyplosz (1994) have highlighted that both inflows and outflows increased as European unemployment soared in the 1970s and 1980s, with increased inflows leading increased unemployment.

6 Relation to the Economics of Unemployment Flows

The preceding empirical analysis has documented a set of stylized facts on unemployment flows across developed economies. How do our findings relate to current understanding of the economics of unemployment flows? On some of these findings the economics is clear. For example, the observation that average unemployment flows are much lower in Continental Europe confirms the diagnosis that European labor markets are *sclerotic*, in the sense that they display much lower rates of reallocation of labor.³⁰ Intuitively, more stringent employment protection in Europe renders firing workers more costly. Since the work of Bentolila and Bertola (1990), it is well understood that such firing costs depress both the rate of firing, as well as the rate of hiring, as firms anticipate their inability to shed newly hired workers in the future.

Our empirical findings are also consistent with the implications of existing models with respect to the dynamics of unemployment inflows. The Mortensen and Pissarides (1994) model of endogenous job destruction predicts that job destruction, and hence inflows into unemployment, spike upward in the immediate onset of a recession.³¹ Intuitively, firms can shed workers immediately in a recession, but hiring in a recovery takes time. The evidence reported in Section 5 that shows that inflows lead changes in unemployment is consistent with this feature of the model.

What can appear less intuitive is the observation that variation in rates of inflow account for a greater proportion of unemployment variation in Europe. Shouldn't the presence of firing costs in Europe depress the variability of layoffs, and hence limit the contribution of the inflow rate to changes in unemployment? In what follows, we show that, in fact, existing models of unemployment flows do not necessarily have this implication.

To illustrate this point, we present a simple model in the vein of Mortensen and Pissarides (1994). For simplicity, there are two labor force states: employment and unemployment. Worker-firm matches yield a flow product of px , where p reflects economy-wide labor productivity, and $x \in [0, 1]$ is an idiosyncratic shock to the match that is distributed according to a distribution function $G(x)$. The value of a match of productivity px to a firm is denoted $J(px)$. As in Mortensen and Pissarides [1994], new matches are created at maximum idiosyncratic productivity, $x = 1$,³² and incur a hiring cost $c(f)$. The hiring cost

³⁰See, among others, Blanchard and Summers [1986], Bertola and Rogerson [1997], Blanchard and Wolfers [2000], and Blanchard and Portugal [2001].

³¹The implied dynamics of unemployment flows are drawn out in detail in Mortensen (1994).

³²Pissarides (2000, Chapter 2) justifies this by assuming that firms are able to choose their technology

is increasing in the outflow rate from unemployment f to capture the notion that it is harder to fill vacancies in tighter labor markets.³³ Firms may also choose to destroy the match at any point in time and incur a firing cost equal to ϕ . It is simple to show that optimal hiring and firing are governed by the conditions:

$$J(p) = c(f), \quad (20)$$

$$J(pR) = -\phi, \quad (21)$$

where R is the reservation idiosyncratic productivity level below which jobs are destroyed. Intuitively, equation (20) states that the value of a new hire to a firm $J(p)$ must equal the marginal cost of hiring an additional worker $c(f)$. Similarly, equation (21) stipulates that the value of a job on the margin of being destroyed, i.e. with idiosyncratic productivity $x = R$, must equal the cost of firing an additional worker $-\phi$. Note that the unemployment inflow rate is given by $s = G(R)$, so that changes in R drive variation in the inflow rate.

To derive the model's implications for the volatility of the inflow rate, log differentiation of (21) implies

$$\frac{d \ln s}{d \ln p} = -\varepsilon_{sR}, \quad (22)$$

where ε_{sR} is the elasticity of the inflow rate with respect to the reservation productivity. Intuitively, following an increase in aggregate productivity p , a job on the margin of being destroyed becomes productive. Firms reduce their reservation productivity R , and the inflow rate declines. By how much the inflow rate declines depends on the degree to which a reduction in R maps into a reduction in s . Note that the volatility of the inflow rate does not depend directly on the size of the firing cost ϕ . Rather it depends on the distribution of idiosyncratic shocks, since $s = G(R)$.

A similar exercise can be used to derive the volatility of the outflow rate using (20):

$$\frac{d \ln f}{d \ln p} = \varepsilon_{Jp} / \varepsilon_{cf}, \quad (23)$$

where ε_{Jp} is the elasticity of the value of a new hire $J(p)$ with respect to aggregate pro-

upon creation of a new job, so that they choose the most productive. Mortensen and Nagypal (2008) present a modification of the Mortensen-Pissarides model that relaxes this assumption while preserving its basic implications.

³³In the Mortensen and Pissarides model, $c(f) = c/q$, where c is the flow cost of a vacancy and q is the job filling rate. For conventional specifications of the matching function, it is simple to rewrite the hiring cost as an increasing function of the job finding rate f .

ductivity p , and ε_{cf} the elasticity of the hiring cost $c(f)$ with respect to the outflow rate f . Again, this is intuitive: On the one hand, an increase in aggregate labor demand raises the value of a new hire, stimulating hiring, and raising the outflow rate from unemployment f . On the other, a tighter labor market raises the cost of hiring, which attenuates the increase in f . The interplay of these two forces determines the volatility of the outflow rate.

Combining equations (22) and (23) reveals that the relative volatility of s and f , and hence their contributions to unemployment variation, depends on the three elasticities ε_{sR} , ε_{Jp} and ε_{cf} . We know relatively little about these elasticities across countries. As mentioned above, ε_{sR} depends on the form of idiosyncratic shocks facing employment relationships. ε_{cf} will depend on the properties of the matching technology in an economy. And ε_{Jp} will depend on the nature of the production technology, and of product demand. Further research on these components would help us better understand the effect of labor market institutions on the magnitude of cyclical fluctuations in the unemployment rate.

For now, though, we note one particular implication of the above framework that would tend to predict a greater role for unemployment inflows in Europe. The elasticity of the value of a new hire with respect to aggregate productivity ε_{Jp} will decline the higher is worker bargaining power. Specifically, if workers have a Nash bargaining weight β , then $\varepsilon_{Jp} = (1 - \beta) p/c(f)$.³⁴ The intuition is straightforward: If workers have greater bargaining power, increases in aggregate labor demand are soaked up primarily by higher wages, limiting incentives for firms to create new jobs, and thereby reducing the variability of the outflow rate f . Viewed in this context, the greater contribution of the inflow rate to changes in unemployment in Europe is consistent with the greater prominence of unions in European labor markets.

7 Conclusion

Our analysis of publicly available data from the OECD provides five contributions to our understanding of unemployment flows. First, we present a method of estimating the flow hazard rates for entering and exiting unemployment across fourteen developed economies, building on the method pioneered by Shimer (2007) for the U.S. An important benefit of this methodology is that it can be extended to estimate unemployment flows for additional economies over longer time periods as more data becomes available.

³⁴To see this, note that in the Mortensen and Pissarides model, $J'(p) = (1 - \beta)$. Combining this with equation (20) yields $\varepsilon_{Jp} \equiv J'(p) p/J(p) = (1 - \beta) p/c(f)$.

Application of this method to fourteen OECD countries uncovers a stark contrast in average flow hazard rates between Anglo-Saxon, Nordic, and Continental European countries. Anglo-Saxon and Nordic labor markets are characterized by high unemployment inflow and outflow rates, while these flow hazard rates in Continental European economies are generally less than half of those in their Anglo-Saxon counterparts. Notably, results for the U.S. which have received much attention in recent literature are a conspicuous outlier among developed economies, with inflow and outflow rates that are at least fifty percent larger than the remaining economies in our sample. These results strengthen and extend earlier work that has diagnosed European labor markets as *sclerotic* based on similar findings for subsets of the economies we study.

Our second contribution is to devise a decomposition of unemployment fluctuations into parts due to changes in inflow and outflow rates that can be applied to countries with very different unemployment dynamics. Conventional decompositions applied to U.S. data have exploited the fact that unemployment is closely approximated by its steady-state value in the U.S. (Elsby, Michaels, and Solon [2009]; Fujita and Ramey [2009]). For many OECD countries outside the U.S., however, we demonstrate that unemployment deviates considerably from its steady-state level. Consequently we show that conventional decompositions lead to misleading results on the relative importance of fluctuations in inflow and outflow rates for the dynamics of the unemployment rate. The results from applying our alternative decomposition reveal approximately a 20:80 inflow/outflow contribution to unemployment variation among Anglo-Saxon countries, whereas in most European countries the split is much closer to 50:50.

Our third contribution is based on a simple correlation analysis of changes in worker flows and changes in the unemployment rate over time. For all countries in our sample, worker flows tend to increase when unemployment increases. Moreover, we find that, in almost all countries in our sample, changes in inflows into unemployment lead changes in the unemployment rate, while changes in outflows tend to lag unemployment variation. This confirms and reinforces the conclusions of previous literature based on a smaller set of countries, suggesting that these findings for worker flows are a stylized fact of modern labor markets.

Stepping back, our empirical findings provide an important perspective on the theoretical literature on unemployment flows that has evolved in recent years. Much of this recent literature has assumed the inflow rate into unemployment to be an exogenous constant. As a reaction to this, a number of studies of U.S. unemployment flows has cautioned against

this trend (Elsby, Michaels, and Solon [2008], Fujita and Ramey [2009], and Yashiv [2007]). A fourth contribution of the results of this paper is that the same conclusion extends to the analysis of labor markets in a wide range of developed economies, and especially so if one is interested in understanding the substantial changes in unemployment rates in Europe.

Our final contribution is to provide some perspective on how our empirical findings relate to modern theoretical models of unemployment dynamics. A common intuition is that the presence of stringent employment protection in Europe raises the cost of firing workers, and hence limits the potential role of changes in inflows in unemployment variation. We present a simple model in the vein of Mortensen and Pissarides (1994) that reveals that this intuition is deceptive. We show that, rather than depending on the magnitude of firing costs, the relative role of inflows in unemployment variation is determined by factors such as the nature of idiosyncratic shocks facing firms, the technology that matches unemployed workers to vacancies, the forms of the production technology and product demand, and the magnitude of worker bargaining power. Of these, only the latter is relatively well-understood across countries. The model implies that higher union bargaining power in Europe depresses the sensitivity of job creation, and hence the role of changes in the outflow rate for unemployment fluctuations, consistent with our empirical results. Future research should seek to gain a complete understanding of these determinants of unemployment volatility across countries to enrich our understanding of the sensitivity of unemployment rates to fluctuations in overall economic activity, and of how this sensitivity is affected by labor market institutions and regulations.

A Mathematical details

Estimation of Outflow Rates. Define the fraction of the labor force that has been unemployed in month t for less than a month as $u_{1,t}$, more than one but less than three months as $u_{3,t}$, more than three but less than six months as $u_{6,t}$, more than six but less than twelve months $u_{12,t}$, and more than 12 months as $u_{\infty,t}$. Then $u_t^{<1} = u_{1,t}$, $u_t^{<3} = u_{1,t} + u_{3,t}$, etc. Given this data and quarterly data for the unemployment rate, the four estimates of the outflow rate are

$$\begin{aligned} f_t^{<1} &= -\ln(u_{3,t} + u_{6,t} + u_{12,t} + u_{\infty,t}) + \left(\frac{2}{3} \ln(u_{1,t} + u_{3,t} + u_{6,t} + u_{12,t} + u_{\infty,t}) + \frac{1}{3} \ln u_{t-3} \right), \\ f_t^{<3} &= -(\ln(u_{6,t} + u_{12,t} + u_{\infty,t}) - \ln u_{t-3}) / 3, \\ f_t^{<6} &= -(\ln(u_{12,t} + u_{\infty,t}) - \ln u_{t-6}) / 6, \text{ and} \\ f_t^{<12} &= -(\ln(u_{\infty,t}) - \ln u_{t-12}) / 12. \end{aligned} \tag{24}$$

In practice, we have annualized data for the duration distribution of unemployment for which we do not know in which month of the year they are measures. Therefore, for our estimates of the outflow rates average the lagged unemployment rates, u_{t-3} , u_{t-6} , and u_{t-12} over the four quarters in the year for which the outflow rate is estimated.

Asymptotic Distribution of Outflow Rate Estimates. We do not observe the $u_{1,t}$, $u_{3,t}$, $u_{6,t}$, $u_{12,t}$, and $u_{\infty,t}$. Instead we observe their sample approximations based on the labor force surveys of the different countries. Let the sample size of the labor force survey be n_t and let $\hat{u}_{d,t}$ $d = 1, 3, 6, 12, \infty$ be the estimated fractions from the labor market survey. Moreover, we also observe the estimated unemployment rate \hat{u}_t , not only at t but also at \hat{u}_{t-3} , \hat{u}_{t-6} , and \hat{u}_{t-12} . We assume that the sample of individuals in the labor force survey is independent across these realizations of the unemployment rate and is of the same size $n_t = n_{t-s}$ where $s = 3, 6, 12$ and the sample sizes are as given in Table 1.

These sample approximations have a joint multinomial distribution, such that

$$E(\hat{u}_{d,t}) = u_{d,t} \text{ and } E(\hat{u}_{t-s}) = u_{t-s} \text{ for } s = 0, 3, 6, 12. \tag{25}$$

and

$$\text{var}(\hat{u}_{d,t}) = \frac{1}{n} u_{d,t} (1 - u_d) \text{ and } \text{cov}(\hat{u}_d, \hat{u}_{d'}) = -\frac{1}{n} \hat{u}_d \hat{u}_{d'} \tag{26}$$

as well as

$$\text{var}(\hat{u}_{t-s}) = \frac{1}{n} u_{t-s} (1 - u_{t-s}) \text{ and } \text{cov}(\hat{u}_{d,t}, \hat{u}_{t-s}) = 0 \text{ for } s = 3, 6, 12, \tag{27}$$

and

$$\text{cov}(\hat{u}_t, \hat{u}_{t-s}) = 0 \text{ for } s \neq 0. \tag{28}$$

Define the vector

$$\mathbf{u}_t = \left[u_{1,t} \quad u_{3,t} \quad u_{6,t} \quad u_{12,t} \quad u_{\infty,t} \quad u_{t-3} \quad u_{t-6} \quad u_{t-12} \right]' \tag{29}$$

and the covariance matrix

$$\mathbf{V}_t = \begin{bmatrix} \mathbf{V}_t^{(d)} & \mathbf{0}_{5 \times 3} \\ \mathbf{0}_{3 \times 5} & \mathbf{V}_t^{(u)} \end{bmatrix}, \tag{30}$$

where

$$\mathbf{V}_t^{(d)} = \begin{bmatrix} u_{1,t}(1-u_{1,t}) & -u_{1,t}u_{3,t} & -u_{1,t}u_{6,t} & -u_{1,t}u_{12,t} & -u_{1,t}u_{\infty,t} \\ -u_{1,t}u_{3,t} & u_{3,t}(1-u_{3,t}) & -u_{3,t}u_{6,t} & -u_{3,t}u_{12,t} & -u_{3,t}u_{\infty,t} \\ -u_{1,t}u_{6,t} & -u_{3,t}u_{6,t} & u_{6,t}(1-u_{6,t}) & -u_{6,t}u_{12,t} & -u_{6,t}u_{\infty,t} \\ -u_{1,t}u_{12,t} & -u_{3,t}u_{12,t} & -u_{6,t}u_{12,t} & u_{12,t}(1-u_{12,t}) & -u_{12,t}u_{\infty,t} \\ -u_{1,t}u_{\infty,t} & -u_{3,t}u_{\infty,t} & -u_{6,t}u_{\infty,t} & -u_{12,t}u_{\infty,t} & u_{\infty,t}(1-u_{\infty,t}) \end{bmatrix}, \quad (31)$$

and

$$\mathbf{V}_t^{(u)} = \begin{bmatrix} u_{t-3}(1-u_{t-3}) & 0 & 0 \\ 0 & u_{t-6}(1-u_{t-6}) & 0 \\ 0 & 0 & u_{t-12}(1-u_{t-12}) \end{bmatrix} \quad (32)$$

and the off-diagonal zero matrices reflect that we assume independence of different samples in the labor force surveys.

Assuming a relatively large sample of the labor force survey, n_t , we can approximate

$$\sqrt{n_t}(\hat{\mathbf{u}}_t - \mathbf{u}_t) \xrightarrow{D} N(\mathbf{0}, \mathbf{V}_t) \quad (33)$$

such that

$$\hat{\mathbf{u}}_t \sim N\left(\mathbf{u}_t, \frac{1}{n_t}\mathbf{V}_t\right) \quad (34)$$

We are not interested in this distribution. Instead, we are interested in three estimates of the outflow rate, each of which is a consistent estimate if there is no duration dependence in the outflow rate during the first year of unemployment. Define the vector

$$\mathbf{f}_t = [f_t^{<1} \quad f_t^{<3} \quad f_t^{<6} \quad f_t^{<12}]' \quad (35)$$

then we will use the Delta-method to derive the asymptotic distribution of $\hat{\mathbf{f}}_t$ for $n \rightarrow \infty$.³⁵ In order to do so, we consider the following gradient.

$$\mathbf{D}_{f,t} = \frac{\partial \mathbf{f}_t}{\partial \mathbf{u}_t'} = - \begin{bmatrix} \frac{2}{3u_t} & 0 & 0 & 0 \\ \frac{2}{3u_t} - \frac{1}{u_t - u_t^{<1}} & 0 & 0 & 0 \\ \frac{2}{3u_t} - \frac{1}{u_t - u_t^{<1}} & -\frac{1}{3(u_t - u_t^{<3})} & 0 & 0 \\ \frac{2}{3u_t} - \frac{1}{u_t - u_t^{<1}} & -\frac{1}{3(u_t - u_t^{<3})} & -\frac{1}{6(u_t - u_t^{<6})} & 0 \\ \frac{2}{3u_t} - \frac{1}{u_t - u_t^{<1}} & -\frac{1}{3(u_t - u_t^{<3})} & -\frac{1}{6(u_t - u_t^{<6})} & -\frac{1}{12(u_t - u_t^{<12})} \\ \frac{1}{3u_{t-3}} & \frac{1}{3u_{t-3}} & 0 & 0 \\ 0 & 0 & \frac{1}{6u_{t-6}} & 0 \\ 0 & 0 & 0 & \frac{1}{12u_{t-12}} \end{bmatrix}' \quad (36)$$

This allows us to write the approximate distribution of $\hat{\mathbf{f}}_t$ as

$$\hat{\mathbf{f}}_t \sim N\left(\mathbf{f}_t, \frac{1}{n}\mathbf{D}_{f,t}\mathbf{V}_t\mathbf{D}_{f,t}'\right) \quad (37)$$

³⁵Note that we assume that the level of unemployment, u_t , is measured without any measurement error.

It is this distribution that we are going to use for the derivation of our hypothesis test as well as for the calculation of the "optimal" weighting of the different outflow rate estimates for our estimated outflow rate.

Hypothesis Test for No Duration Dependence. If there is no duration dependence, then it is the case that

$$H_0 : \mathbf{f}_t = f\boldsymbol{\iota}, \text{ where } f \text{ is scalar and } \boldsymbol{\iota} \text{ is a vector with ones} \quad (38)$$

which is the null-hypothesis of interest. For our test, we define the matrix

$$\mathbf{M}_f = \begin{bmatrix} 1 & 0 & 0 & -1 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & -1 \end{bmatrix} \quad (39)$$

Under the null-hypothesis, it is the case that

$$\mathbf{M}_f \widehat{\mathbf{f}}_t \sim N \left(\mathbf{0}, \frac{1}{n} \mathbf{M}_f \mathbf{D}_{f,t} \mathbf{V}_t \mathbf{D}'_{f,t} \mathbf{M}'_f \right) \quad (40)$$

Define the Choleski-decomposition matrix \mathbf{C} as

$$\mathbf{M}_f \mathbf{D}_{f,t} \mathbf{V}_t \mathbf{D}'_{f,t} \mathbf{M}'_f = \mathbf{C}_t \mathbf{C}'_t \quad (41)$$

Then

$$\sqrt{n} \mathbf{C}_t^{-1} \mathbf{M}_f \widehat{\mathbf{f}}_t \sim N(\mathbf{0}, \mathbf{I}_3) \quad (42)$$

Remember that the sum of squares of 3 independent standard normally distributed random variables is chi-squared distributed with 3 degrees of freedom. Hence, when we define

$$\begin{aligned} g_t &= n \widehat{\mathbf{f}}'_t \mathbf{M}'_f (\mathbf{C}'_t)^{-1} \mathbf{C}_t^{-1} \mathbf{M}_f \widehat{\mathbf{f}}_t \\ &= n \widehat{\mathbf{f}}'_t \mathbf{M}'_f (\mathbf{M}_f \mathbf{D}_{f,t} \mathbf{V}_t \mathbf{D}'_{f,t} \mathbf{M}'_f)^{-1} \mathbf{M}_f \widehat{\mathbf{f}}_t \end{aligned} \quad (43)$$

then, under the null it is the case that

$$g_t \sim \chi^2(3). \quad (44)$$

Optimal Weighting of Estimated Outflow Rates. For those countries for which we do not reject the null-hypothesis for reasonably large sample sizes and for the majority of the years, we then have to decide on the optimal weighting of the estimated finding rates. That is, we want to find vector with weights, \mathbf{w} , and estimate

$$\widehat{f}_t = \mathbf{w}'_t \widehat{\mathbf{f}}_t \quad (45)$$

such that

$$\mathbf{w}'_t \boldsymbol{\iota} = 1 \quad (46)$$

and that, given this constraint, \mathbf{w} minimizes

$$V_{f,t} = \mathbf{w}'_t \mathbf{D}_{f,t} \mathbf{V}_t \mathbf{D}'_{f,t} \mathbf{w}_t \quad (47)$$

Let us first take care of the restriction. For this purpose, define

$$\tilde{\mathbf{w}}_t = [w_t^{<1} \quad w_t^{<3} \quad w_t^{<6}]' \quad (48)$$

such that

$$\mathbf{w}_t = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix} + \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ -1 & -1 & -1 \end{bmatrix} \tilde{\mathbf{w}}_t \quad (49)$$

$$= \mathbf{e}_1 + \mathbf{M}_w \tilde{\mathbf{w}}_t \quad (50)$$

Then the objective function can be written as

$$V_{f,t} = \mathbf{e}'_1 \mathbf{D}_{f,t} \mathbf{V}_t \mathbf{D}'_{f,t} \mathbf{e}_1 + 2\mathbf{e}'_1 \mathbf{D}_{f,t} \mathbf{V}_t \mathbf{D}'_{f,t} \mathbf{M}_w \tilde{\mathbf{w}}_t + \tilde{\mathbf{w}}'_t \mathbf{M}'_w \mathbf{D}_{f,t} \mathbf{V}_t \mathbf{D}'_{f,t} \mathbf{M}_w \tilde{\mathbf{w}}_t \quad (51)$$

which yields that the set of optimal weights is

$$\tilde{\mathbf{w}}_t = - (\mathbf{M}'_w \mathbf{D}_{f,t} \mathbf{V}_t \mathbf{D}'_{f,t} \mathbf{M}_w)^{-1} \mathbf{M}'_w \mathbf{D}_{f,t} \mathbf{V}_t \mathbf{D}'_{f,t} \mathbf{e}_1 \quad (52)$$

and thus

$$\mathbf{w}_t = \mathbf{e}_1 - \mathbf{M}_w (\mathbf{M}'_w \mathbf{D}_{f,t} \mathbf{V}_t \mathbf{D}'_{f,t} \mathbf{M}_w)^{-1} \mathbf{M}'_w \mathbf{D}_{f,t} \mathbf{V}_t \mathbf{D}'_{f,t} \mathbf{e}_1 \quad (53)$$

Note, this only imposes that the weights add up to one but not that they are positive.

Dynamic Decomposition of Changes in Unemployment. Note that the unemployment rate at the end of year t evolves according to

$$u_t = \lambda_t u_t^* + (1 - \lambda_t) u_{t-1}, \quad (54)$$

where $\lambda_t \equiv 1 - e^{-12(s_t+f_t)}$ is the annual rate of convergence to steady state, $u_t^* \equiv s_t/(s_t + f_t)$ is the steady state unemployment rate, and s_t and f_t are respectively the monthly unemployment inflow and outflow hazard rates in year t . A log-linear approximation to (54) around $s_t = s_{t-1}$, $f_t = f_{t-1}$, and $u_{t-1} = u_{t-1}^*$ is given by

$$\ln u_t \approx \ln u_{t-1}^* + \lambda_{t-1} (\ln u_t^* - \ln u_{t-1}^*) + (1 - \lambda_{t-1}) (\ln u_{t-1} - \ln u_{t-1}^*) \quad (55)$$

$$\approx \ln u_{t-1}^* + \lambda_{t-1} (1 - u_{t-1}^*) [\Delta \ln s_t - \Delta \ln f_t] + (1 - \lambda_{t-1}) (\ln u_{t-1} - \ln u_{t-1}^*). \quad (56)$$

If unemployment is always in steady state, then

$$\Delta \ln u_t = \Delta \ln u_t^* \approx (1 - u_{t-1}^*) [\Delta \ln s_t - \Delta \ln f_t] \quad (57)$$

However, if unemployment deviates from steady state, then this approximation is not appropriate.

In that case, it is worthwhile to realize that

$$\begin{aligned}
\ln u_t - \ln u_{t-1} &= \lambda_{t-1} (\ln u_t^* - \ln u_{t-1}^*) - \lambda_{t-1} (\ln u_{t-1} - \ln u_{t-1}^*) \\
&= \lambda_{t-1} (\ln u_t^* - \ln u_{t-1}^*) - \lambda_{t-1} (\ln u_t - \ln u_{t-1}^*) + \lambda_{t-1} (\ln u_t - \ln u_{t-1}) \\
&= -\lambda_{t-1} (\ln u_t - \ln u_t^*) + \lambda_{t-1} (\ln u_t - \ln u_{t-1})
\end{aligned} \tag{58}$$

such that

$$\Delta \ln u_t \approx -\frac{\lambda_{t-1}}{1 - \lambda_{t-1}} (\ln u_t - \ln u_t^*) \tag{59}$$

and thus

$$(\ln u_t - \ln u_t^*) = -\frac{1 - \lambda_{t-1}}{\lambda_{t-1}} \Delta \ln u_t \tag{60}$$

Substituting this into (55) we can write

$$\Delta \ln u_t \approx \lambda_{t-1} \left\{ (1 - u_{t-1}^*) [\Delta \ln s_t - \Delta \ln f_t] + \frac{1 - \lambda_{t-2}}{\lambda_{t-2}} \Delta \ln u_{t-1} \right\}. \tag{61}$$

Which allows us to do the decomposition out of steady state.

Effect of Inclusion of Non-Participants. Equation (1) does not take into account flows that stem from people that are not-in-the-labor-force (NILF) that start looking for a job and become unemployed. It also does not include persons that flow out of unemployment as well as out of the labor force. In addition, it normalizes the size of the labor force to one, thus not taking into account labor force growth. We have actually calculated a set of results that allow for these things, but for the sake of clarity have abstracted from them in the analytical framework applied here. It turns out that including these things does not affect the results much. Below we explain why.

The first thing to note is that our estimates of the outflow rate out of unemployment solely use unemployment data and are not affected by the simplifying assumptions described above. The outflow rate basically determines the total outflows out of unemployment. Since the change in the number of unemployed persons is the difference between the inflows and the outflows, this implies that the total inflows into unemployment are also not sensitive to these simplifying assumptions. The only thing that is affected is the inflow rate. In our framework, the inflow rate reflects the fraction of employed persons that flows into unemployment. Without the simplifying assumption the inflow rate would reflect the fraction of persons that are either employed or NILF that flow into unemployment. In effect, if one would drop our simplifying assumption one would find a lower inflow rate that is scaled down by the labor force participation rate. For all countries in the sample, labor force growth is so small that it is swamped by the magnitude of worker flows. Hence, the results presented here turn out to be almost identical to the ones that take into account labor force growth.

Table 1: Approximate sample sizes of Labor Force Surveys

Australia: Survey covers about 0.5% of Australia's population. (We use $n = 57,000$.)

Canada: Approximately 56,000 households since 1976. (We use $n = 135,000$.)

France: Data are compiled from various sources including the Labor Force Survey ("Employment Survey"). Since 2003, the Survey is quarterly and continuous. Previously, the Survey was annual. In March 2001, 75,000 households responded to the survey covering 150,000 persons which includes armed forces. (We use $n = 150,000$.)

Germany: The average quarterly sample in 2005 comprises about 165,000 respondents. (We use $n = 165,000$.)

Ireland: Sample of 39,000 households is surveyed each quarter. Includes career military living in private households. (We use $n = 97,500$.)

Italy: The sample was doubled in April 1990 from 12,000 to 24,000 households. (We use $n = 60,000$.)

Japan: The survey covers a sample of 40,000 households. (We use $n = 100,000$.)

New Zealand: Obtained from 16,000 private dwellings (approximately 32,000 persons) each quarter. From 2nd quarter of 1995, residents in non-private households are excluded from the sample. (We use $n = 40,000$.)

Norway: Sample size is 12,000 households (24,000 persons). Includes all armed forces.(We use $n = 24,000$.)

Portugal: Sample size approximately 21,000 households. (We use $n = 52,500$.)

Spain: Sample includes 74,000 households; however in practice only about 65,000 households (i.e. approximately 185,000 persons) are interviewed. (We use $n = 185,000$.)

Sweden: Participation is voluntary. Every month about 20,000 persons are included in the sample. (We use $n = 20,000$.)

United Kingdom: Survey is conducted continuously throughout the year. In any three-month period, 57,000 households are interviewed (120,000 persons). (We use $n = 120,000$.)

United States: Data comes from the monthly CPS. Each month about 60,000 households are interviewed for the survey. (We use $n = 130,000$.)

Note: Sample sizes include non-labor force members. Information based on metadata for OECD (2008b), available at <http://stats.oecd.org/mci/default.asp?lang=en&subject=10>.

Table 2: Test for no duration dependence and summary statistics on unemployment and flow rates

Country	Start of sample	Test for no duration dependence			Sample averages		
		P-value $f^{<1}$ included	P-value $f^{<1}$ excluded	H0 Rejected?	Unemployment rate (u)	Outflow rate (f)	Inflow rate (s)
Australia	1978	0%	0%	■	7.3%	22.3%	1.7%
Canada	1976	0%	0%	■	8.6%	25.8%	2.3%
France	1975	0%	9%		9.1%	7.8%	0.8%
Germany	1983	4%	4%		7.9%	6.0%	0.5%
Ireland	1983	2%	6%		10.9%	5.8%	0.6%
Italy	1983	10%	13%		10.1%	4.1%	0.4%
Japan	1977	0%	0%	■	3.2%	19.3%	0.6%
New Zealand	1986	0%	0%	■	6.3%	27.9%	1.7%
Norway	1983	0%	0%	■	4.2%	38.3%	1.6%
Portugal	1986	7%	14%		6.1%	6.5%	0.4%
Spain	1977	0%	5%		15.3%	6.2%	1.0%
Sweden	1976	0%	0%	■	4.9%	28.9%	1.3%
United Kingdom	1983	0%	0%	■	7.7%	13.3%	1.0%
United States	1968	0%	0%	■	6.0%	57.5%	3.6%

Note: Reported P-values are sample averages for the test for no duration dependence over the sample period, based on the application of the sample size reported in Table 1. The hypothesis ' $f^{<1}$ included' refers to $H_0: f_t^{<1} = f_t^{<3} = f_t^{<6} = f_t^{<12}$. The hypothesis ' $f^{<1}$ excluded' refers to $H_0: f_t^{<3} = f_t^{<6} = f_t^{<12}$. The rejection of the null of no duration dependence is based on the second hypothesis and determined at a 1% significance level.

Table 3: Decompositions of unemployment fluctuations

Country	std. dev. of % dev. from ss	Steady-state decomposition			Non-steady-state decomposition			
		β_f^*	β_s^*	residual	β_f	β_s	residual	
Australia	1.4%	0.94	0.14	-0.08	0.91	0.12	0.00	-0.03
Canada	0.7%	0.75	0.30	-0.05	0.74	0.29	0.00	-0.02
France	4.6%	0.61	0.59	-0.21	0.49	0.48	0.04	0.00
Germany	9.2%	0.76	0.82	-0.58	0.45	0.60	-0.04	0.00
Ireland	11.5%	1.46	0.51	-0.97	0.77	0.29	-0.03	-0.02
Italy	8.9%	1.19	0.19	-0.37	0.90	0.65	0.06	-0.02
Japan	1.0%	0.56	0.50	-0.06	0.52	0.48	0.00	0.00
New Zealand	1.1%	0.86	0.18	-0.04	0.84	0.17	0.00	-0.01
Norway	0.4%	0.45	0.55	0.00	0.45	0.55	0.01	0.00
Portugal	10.9%	0.69	0.50	-0.19	0.51	0.44	0.02	0.04
Spain	9.5%	0.81	0.40	-0.21	0.62	0.36	0.02	0.00
Sweden	1.6%	0.46	0.58	-0.03	0.45	0.55	0.00	-0.01
United Kingdom	3.0%	0.54	0.58	-0.12	0.57	0.42	0.01	0.01
United States	0.0%	0.82	0.18	-0.01	0.82	0.18	0.00	-0.01

Table 4: Average worker flows and correlations with changes in the unemployment rate

Country	$\frac{1}{2}(F+S)$	$corr(\Delta u_t, \Delta F_{t+k})$			$corr(\Delta u_t, \Delta S_{t+k})$		
		$k = -1$	$k = 0$	$k = 1$	$k = -1$	$k = 0$	$k = 1$
Australia	18.6%	-.6	-.3	.5	-.3	.2	.0
Canada	25.7%	-.2	.0	.6	.0	.4	.3
France	8.2%	.1	.2	.5	.4	.6	.1
Germany	5.6%	-.1	-.2	.6	.5	.6	.2
Ireland	6.2%	.0	-.5	.8	.1	.1	.2
Italy	4.8%	-.2	-.2	.5	.0	.1	.1
Japan	7.0%	.2	.2	.1	.3	.3	-.2
New Zealand	18.8%	.0	-.1	.2	.2	.2	-.1
Norway	18.1%	.1	.4	-.1	.2	.4	-.3
Portugal	4.5%	.0	.0	.6	.4	.4	.2
Spain	10.2%	.1	-.1	.5	.6	.5	.1
Sweden	14.3%	.0	.6	.9	.3	.8	.7
United Kingdom	11.2%	-.5	.1	.6	-.2	.5	.3
United States	40.0%	.2	.0	.3	.5	.4	-.2

Note: The column $\frac{1}{2}(F+S)$ list the average of the average in and outflow rates over the sample period.

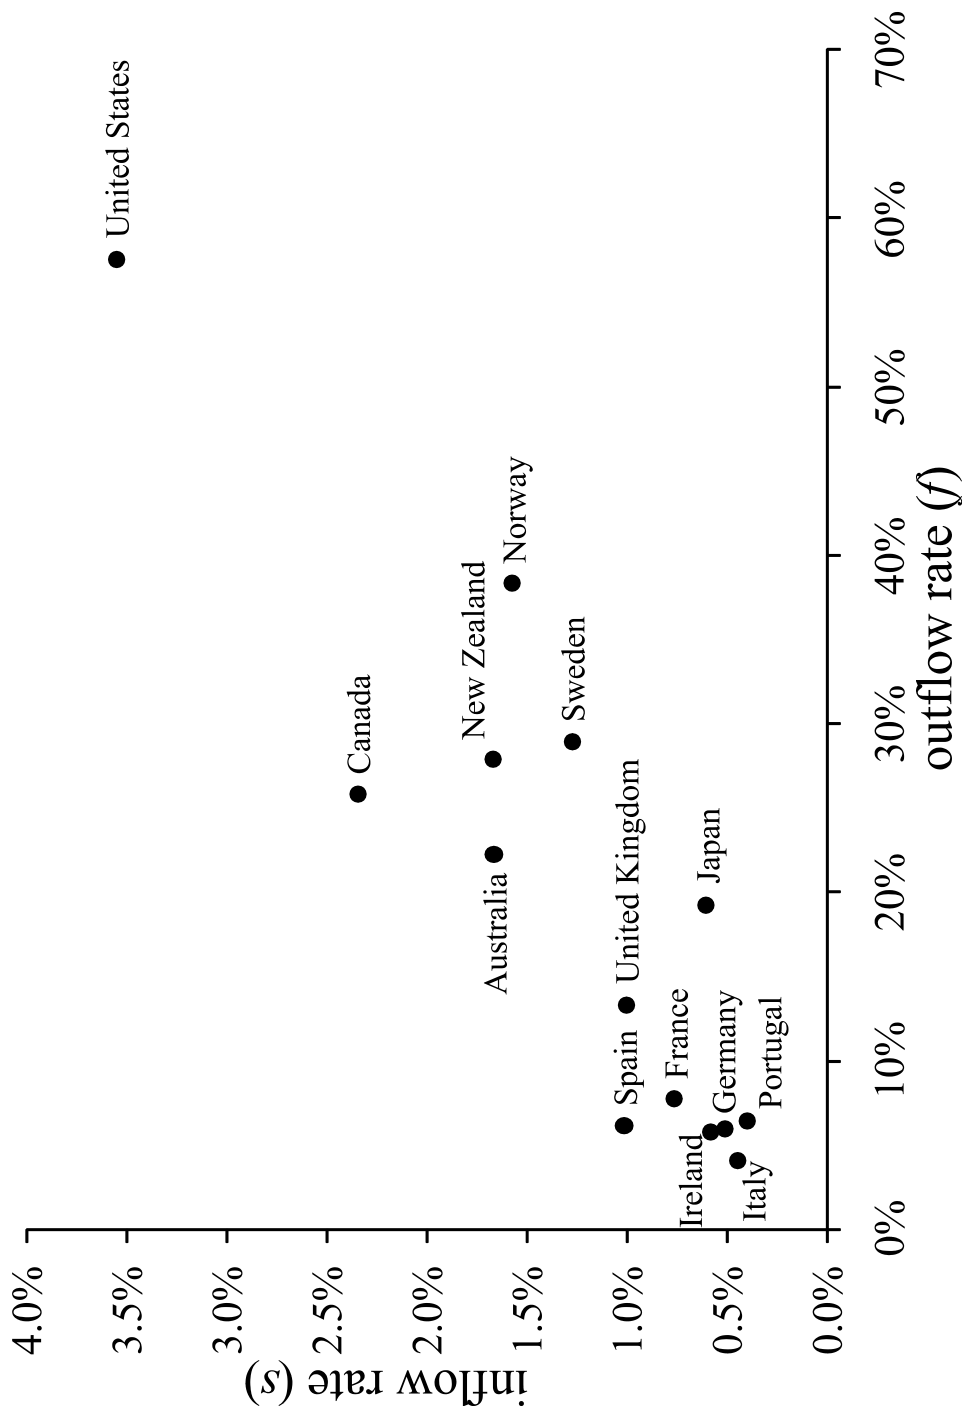

Figure 1: Average in- and outflow rates across countries.
